Abstract

SMPyBandits is a package for numerical simulations on single-player and multi-players Multi-Armed Bandits (MAB) algorithms, written in Python (2 or 3). This library is the most complete open-source implementation of state-of-the-art algorithms tackling various kinds of sequential learning problems referred to as Multi-Armed Bandits. It is extensive, simple to use and maintain, with a clean and well documented codebase. It allows fast prototyping of experiments, with an easy configuration system and command-line options to customize experiments.

Keywords: sequential learning; multi-armed bandit; reinforcement learning; python.

1. Presentation

1.1 Single-Player MAB

Multi-Armed Bandit (MAB) problems are well-studied sequential decision making problems in which an agent repeatedly chooses an action (the “arm” of a one-armed bandit) in order to maximize some total reward (Robbins, 1952), (Lai and Robbins 1985). Initial motivation for their study came from the modeling of clinical trials, as early as 1933 with the seminal work of Thompson (Thompson, 1933), where arms correspond to different treatments with unknown, random effect. Since then, MAB models have been proved useful for many more applications, that range from cognitive radio (Jouini et al. 2009) to online content optimization like news article recommendation (Li et al. 2010), online advertising (Chapelle and Li 2011), A/B Testing (Kaufmann et al. 2014; Yang et al. 2017), or portfolio optimization (Sani et al. 2012).

More formally, a stochastic MAB is defined by $K > 1$ distributions $v_k$ (arms), and i.i.d. rewards $r_k(t) \sim v_k, \forall t$. An agent choose arm $A(t) \in \{1, \ldots, K\}$ at time $t$ and observes the reward $r_{A(t)}(t)$ without knowing the other (hidden) rewards. Her goal is to maximize $\sum_t r_{A(t)}(t)$ by sequentially exploring the $K$ arms, and she essentially has to find and exploit the best one as fast as possible. This library tackles one dimensional distributions, and supports Bernoulli, binomial, Poisson, and a generic discrete distributions, as well as exponential, gamma, Gaussian (of known scale or variance) and uniform continuous distributions, which can be truncated to an interval $[a, b]$ or have unbounded support ($\mathbb{R}$).

SMPyBandits is a complete open-source implementation of single-player bandit algorithms, containing over 65 algorithms. It uses a well-designed hierarchical structure and class inheritance scheme to minimize redundancy in the codebase. For example, many existing algorithms are index-based: they compute an index $I_k(t) \in \mathbb{R}$ for each arm $k$ and simply play $A(t) = \arg\max_k I_k(t)$ at time $t$. As

such, it is easy to write new index-based algorithms by inheriting from the \texttt{IndexPolicy} class, and simply defining one method \texttt{computeIndex(k)} to compute the index $I_k(t)$.

1.2 Multi-Players MAB

For Cognitive Radio and other applications, a well-studied extension is to consider $M \geq 2$ players, interacting on the same $K$ arms. Whenever two or more players select the same arm at the same time, they all suffer from a collision. Different collision models have been proposed, and the simplest one consists in giving a 0 reward to each colliding players. Without any centralized supervision or coordination between players, they must learn to access the $M$ best resources (i.e., arms with highest means) without collisions. \textit{SMPyBandits} implements all collision models found in the literature, as well as all the algorithms from the last 10 years (including \textit{rhoRand}, \textit{MEGA}, \textit{MusicalChair}, and our state-of-the-art algorithms \textit{RandTopM} and \textit{MCTopM} from Besson and Kaufmann (2018b)). For comparison, realistic or full-knowledge centralized algorithms are also implemented.

2. Features

With this numerical framework, simulations can run on a single CPU or a single multi-core machine using \texttt{joblib} (Varoquaux, 2017), and summary plots are automatically saved as high-quality PNG, PDF and EPS, using \texttt{matplotlib} (Hunter 2007) and \texttt{seaborn} (Waskom et al. 2017). Raw data from each simulation is also saved in a HDF5® file using \texttt{h5py} (Collette et al., 2018), an efficient and compressed binary format, to allow easy post-mortem exploration of simulation results. Making new simulations is very easy, one only needs to write a configuration script (\texttt{configuration.py}), without needing a complete knowledge of the internal code architecture.

A complete Sphinx documentation, for each algorithm and all parts of the codebase, even including the constants in the different configuration files, is available here: \url{https://SMPyBandits.GitHub.io}

2.1 How to run experiments?

We show how to install \textit{SMPyBandits}, and an example of how to run a simple experiment. This bash snippet\footnote{See \url{SMPyBandits.GitHub.io/How_to_run_the_code.html} for more details.} shows how to clone the code\footnote{\textit{SMPyBandits} is also available on PyPi, see \url{pypi.org/project/SMPyBandits}. You can install it directly with \texttt{sudo pip install SMPyBandits}, or from a virtualenv.} and install the requirements for Python 3 (once):

\begin{verbatim}
# 1. get the code in the folder you want
$ git clone https://GitHub.com/SMPyBandits/SMPyBandits.git
$ cd SMPyBandits.git
# 2. install the requirements
$ pip install -r requirements.txt

Launching simulations is easy, for instance this snippet shows how to run $N = 1000$ repetitions of a simple non-Bayesian Bernoulli-distributed problem, for $K = 9$ arms, an horizon of $T = 10000$ and on 4 CPUs. Such simulation takes about 20 minutes, on a standard 4-cores 64 bits GNU/Linux laptop. Using environment variables ($N=1000$ etc) in the command line is not required, but it is convenient:

# 3. run a single-player simulation
$ BAYES=False ARM_TYPE=Bernoulli N=1000 T=10000 K=9 N_JOBS=4 \n_ MEANS=[0.1,0.2,0.3,0.4,0.5,0.6,0.7,0.8,0.9] python3 main.py configuration.py
\end{verbatim}
2.2 Example of simulation and illustration

A small script configuration.py is used to import the arm classes, the policy classes and define the problems and the experiments. Choosing the algorithms is easy by customizing the configuration["policies"] list in the configuration.py file. For instance, one can compare the standard anytime klUCB algorithm against the non-anytime variant klUCBPlusPlus algorithm, and also UCB (with $\alpha = 1$) and Thompson (with Beta posterior).

configuration["policies"] = [
    {"archtype": k1UCB, "params": {"klucb": klucbBern}},
    {"archtype": k1UCBPlusPlus, "params": {"horizon": HORIZON, "klucb": klucbBern}},
    {"archtype": UCBalpha, "params": {"alpha": 1.0}},
    {"archtype": Thompson, "params": {"posterior": Beta}}
]

Running the simulation as shown above will save figures in a sub-folder, as well as save data (pulls, rewards and regret) in a HDF5 file³. Figure 1 below shows the average regret for these 4 algorithms. The regret is the difference between the cumulated rewards of the best fixed-armed strategy (which is the oracle strategy for stationary bandits), and the cumulated rewards of the considered algorithms.

Figure 1: Example of a single-player simulation showing the average regret and histogram of regrets of 4 algorithms. They all perform very well: each algorithm is known to be order-optimal (i.e., its regret is proved to match the lower-bound up-to a constant), and each but UCB is known to be optimal (i.e. with the constant matching the lower-bound). For instance, Thomson sampling is very efficient in average (in yellow), and UCB shows a larger variance (in red).

3. Research papers using SMPyBandits

SMPyBandits was used for the following research articles since 2017:

- For Besson and Kaufmann (2018b), we used SMPyBandits for all the simulations for multi-player bandit algorithms.² We designed the two RandTopM and MCTopM algorithms and proved than they enjoy logarithmic regret in the usual setting, and outperform significantly the previous state-of-the-art solutions (i.e., rhoRand, MEGA and MusicalChair).

- In Besson et al. (2018), we used SMPyBandits to illustrate and compare different aggregation algorithms.³ We designed a variant of the Exp3 algorithm for online aggregation (or boosting)

of experts (Bubeck and Cesa-Bianchi, 2012), called Aggregator. Aggregating experts is a well-studied idea in sequential learning and in machine learning in general. We showed that it can be used in practice to select on the run the best bandit algorithm for a certain problem from a fixed pool of experts. This idea and algorithm can have interesting impact for Opportunistic Spectrum Access applications (Jouini et al., 2009) that use multi-armed bandits algorithms for sequential learning and network efficiency optimization.

- In Besson and Kaufmann (2018a), we used SMPyBandits to illustrate and compare different “doubling trick” schemes. In sequential learning, an algorithm is anytime if it does not need to know the horizon $T$ of the experiments. A well-known trick for transforming any non-anytime algorithm to an anytime variant is the “Doubling Trick”: start with an horizon $T_0 \in \mathbb{N}^*$, and when $t > T_i$, use $T_{i+1} = 2T_i$. We studied two generic sequences of growing horizons (geometric and exponential), and we proved two theorems that generalized previous results. A geometric sequence suffices to conserve minimax regret bounds ($R_T = \mathcal{O}(\sqrt{T})$), with a constant multiplicative loss $\ell \leq 4$, but cannot be used to conserve a logarithmic regret bound ($R_T = \mathcal{O}(\log(T))$). An exponential sequence can be used to conserve logarithmic bounds, with a constant multiplicative loss also $\ell \leq 4$ in the usual setting. It is still an open question to know if a well-tuned exponential sequence can conserve minimax bounds, or even “weak” minimax bounds ($R_T = \mathcal{O}(\sqrt{T \log(T)})$).

4. Dependencies

This library is written in Python (Foundation, 2017), for versions 2.7+ or 3.4+, using matplotlib (Hunter, 2007) for 2D plotting, numpy (van der Walt et al., 2011) for data storing, random number generations and operations on arrays, scipy (Jones et al., 2001) for statistical and special functions, and seaborn (Waskom et al., 2017) for pretty plotting and colorblind-aware colormaps.

Optional dependencies include joblib (Varoquaux, 2017) for parallel simulations, numba (Inc. et al., 2017) for automatic speed-up on small functions, sphinx (Brandl et al., 2018) for generating the documentation, and jupyter (Kluyver et al., 2016) used with ipython (Pérez and Granger, 2007) to experiment with the code.
