Abstract

Systems involving both time and concurrency are notoriously difficult to analyze. Existing decidability results apply when clocks on different processes cannot be compared or when the set of timed executions is regular. We prove new decidability results for timed concurrent systems, requiring neither restriction. We consider the formalism of time-constrained MSC-graphs (TC-MSC graphs for short) introduced in [1], and study if the set of timed executions generated by a TC-MSC graph is empty. This emptiness problem is known to be undecidable in general [9]. Our approach consists of finding a regular set $R$ of representative timed executions, i.e., such that every timed execution of the system has an equivalent, up to commutation, timed execution in $R$. This allows us to solve the emptiness problem under the assumption that the TC-MSC graph is prohibited from (1) forcing any basic scenario to take an arbitrarily long time to complete and (2) enforcing unboundedly many events to occur within one unit of time.

Keywords: timed automata, partial order languages, MSC graphs, set of representatives

1. Introduction

In a distributed system, several processes interact to implement a collection of global behaviors. These processes are often equipped with timing information and protocol specifications include timing requirements for messages and descriptions of how to recover from timeouts. Thus, a system designer has to deal with situations where time and concurrency influence each other. One way to describe these interactions is through scenarios, formalized using Message Sequence Charts (MSCs) [12]. The timing information is captured by adding timing constraints between pairs of events, yielding time-constrained MSCs (TC-MSCs). Further, infinite collections of MSCs can be modelled using High-level Message Sequence Charts, or more basic forms called MSC-graphs: directed graphs whose nodes are labelled by MSCs. MSC-graphs can be generalized to time-constrained MSC graphs (TC-MSC graphs)[9], whose nodes are labelled by TC-MSCs and edges have additional timing constraints. In this paper, we focus on decidability results for the analysis of TC-MSC graphs.

Obtaining decidability in the presence of both time and concurrency is a challenging issue. Even the simple yet fundamental question of checking if there exists a timed execution of a TC-MSC graph consistent with all the constraints is undecidable in general [9]. This is the emptiness problem, which in the case of (sequential) timed automata is known to be decidable [3]. Extending such results to distributed systems has been done only in two particular and limited settings. In [13, 8], clocks are local to a process. But then, one cannot specify time taken by a communication (message or synchronisation). This limitation makes the specification formalism very weak. The second setting can relate clocks from different processes and specify how long a communication can take [1, 2, 6, 7]. However, they restrict the concurrency in a structural way, for instance by considering only locally synchronized ([15, 4, 11]) MSC-graphs in [1, 2]) or only safe Petri Nets (in [6, 7]). This forces the set of timed executions defined by the specification to...
be (timed) regular, which is a significant restriction in a concurrent setting where even simple examples may not be regular (e.g., the producer-consumer protocol).

In this paper, we propose a first decidability result for (globally) timed concurrent systems having a possibly non-regular set of behaviors. More specifically, we tackle the emptiness problem for TC-MSC graphs (which is undecidable in general [9]) by coming up with mild restrictions which are practically motivated and yet sufficient to prove decidability. Our technique to obtain decidability is to use a regular set of representatives. A set of representatives is a subset of executions such that every execution of the system has an equivalent execution (up to commutation) in this subset. This technique has been used previously in untimed settings [14, 10] and with the particular set of existentially bounded executions [10] as the regular set of representatives. In Section 3, it is formalized as a general technique on timed languages and applied to the set of well-behaved timed executions, i.e., timed executions where two events from the same scenario do not occur at dates that are arbitrarily apart (non-drifting) and only a limited number of events can occur in a unit of time (non-Zeno).

We state our main theorems in Section 4: the emptiness problem is decidable for well-formed TC-MSC graphs. Intuitively, being well-formed prohibits an unbounded number of events from occurring in a concurrent setting where even simple examples may not be regular (e.g., the producer-consumer protocol). Together, these imply that the emptiness problem is decidable for well-formed TC-MSC graphs. Intuitively, being well-formed prohibits an unbounded number of events from occurring in a concurrent setting where even simple examples may not be regular (e.g., the producer-consumer protocol).

2. Time-Constrained MSC graphs

We fix a finite non-empty set of processes \( \mathcal{P} \) that communicate through messages via reliable FIFO channels. For \( p, q \in \mathcal{P} \), the communication alphabet is \( \Sigma = \{pq, p?q \mid p \neq q\} \) where the send action \( pq \) denotes a message sent from process \( p \) to \( q \) and the receive action \( q?p \) denotes a message received by process \( q \) from \( p \). Let \( \mathbb{N} \) denote the set of natural numbers and \( \mathcal{I}(\mathbb{N}) \) denote the set of open and closed intervals whose end points are in \( \mathbb{N} \), plus the intervals of the form \([c, \infty)\), \((c, \infty)\), where \( c \in \mathbb{N} \). We shall use intervals in \( \mathcal{I}(\mathbb{N}) \) to constrain the lower and upper bounds on the difference of occurrence times of events in a scenario. We remark that in what follows, intervals involving non-negative rationals can be easily simulated by scaling them to integers. We adopt the basic definitions from [1].

**Definition 2.1.** A time-constrained message sequence chart (TC-MSC) over \( \mathcal{P} \) and \( \Sigma \) is a tuple 

\[ T = (E, \prec p \in \mathcal{P}, \lambda, \mu, \delta) \]

where \( E \) is a finite non-empty set of events; \( \lambda : E \rightarrow \Sigma \) labels each event with an action type in \( \Sigma \) such that:

(i) Each \( \prec \subseteq E_p \times E_p \) is a total order, where \( E_p = \lambda^{-1}(\{p\} \times \{!, ?\} \times \mathcal{P}) \). Members of \( E_p \) are termed \( p \)-events.

(ii) The message relation \( \mu \) is a bijection from \( E_{\text{send}} = \lambda^{-1}(\mathcal{P} \times \{!\} \times \mathcal{P}) \) (send events) to \( E_{\text{recv}} = \lambda^{-1}(\mathcal{P} \times \{?\} \times \mathcal{P}) \) (receive events).

For any \( e, f \) with \( \mu(e) = f \), for some \( p, q \), we have \( \lambda(e) = pq \) and \( \lambda(f) = q?p \). For each \( e, e' \) with \( \lambda(e) = \lambda(e') = pq \) for some \( p \in \mathcal{P} \), we have \( e \prec p e' \) iff \( \mu(e) < \mu(e') \). (FIFO)

(iii) Writing \( < \) for the transitive closure of \( \bigcup_{p \in \mathcal{P}} \prec p \cup \mu \), the time constraint labelling function \( \delta \) associates an interval in \( \mathcal{I}(\mathbb{N}) \) to each pair of events \( e, f \) in \( E \times E \) with \( e < f \).

With a slight abuse of notation, we write a TC-MSC as \( T = (E, <, \lambda, \mu, \delta) \) with \( < \) as above. A linearization of \( T \) is a sequence \( \sigma = a_1 \ldots a_\ell \) over \( \Sigma^* \), where \( \ell = |E| \) and such that \( E \) can be enumerated as \( e_1 \ldots e_\ell \) with \( a_i = \lambda(e_i) \), and \( e_i < e_j \) implies \( i < j \) for any \( i, j \) in \( \{1, \ldots, \ell\} \). Note that due to the FIFO condition (see Condition (ii) in the definition above), the enumeration \( e_1 \ldots e_\ell \) is uniquely determined by \( a_1 \ldots a_\ell \). A TC-MSC \( T \) defines a collection of linearizations augmented with occurrence times such that the relative delay between each pair of causally ordered events falls within the interval...
dictated by $\delta$. To avoid confusion, we shall term occurrence times as *dates*: A *timed execution* $w$ of $T$ is a sequence $(a_1, d_1) \ldots (a_\ell, d_\ell)$, where $a_1 \ldots a_\ell$ is a linearization of $T$, each date $d_i$ is a non-negative real for $i = 1, \ldots, \ell$, and $d_1 \leq \ldots \leq d_\ell$. Let $e_1 \ldots e_\ell$ be the enumeration corresponding to the linearization $a_1 \ldots a_\ell$. Then $e_i < e_j$ implies $d_j - d_i$ is in the interval $[\delta(e_i, e_j)$.

To describe infinite collections of TC-MSCs, we use TC-MSC graphs:

**Definition 2.2.** Let $T$ be a finite non-empty set of TC-MSCs. A TC-MSC graph over $T$ is a tuple $G = (N, \rightarrow, n_{ini}, N_{fin}, \Lambda, \Delta)$ where $N$ is a finite set of nodes, $\rightarrow \subseteq N \times N$ a transition relation, $n_{ini} \in N$ the initial node, $N_{fin} \subseteq N$ the subset of final nodes, and $\Lambda : N \rightarrow T$ labels each node with a TC-MSC from $T$. Further, the mapping $\Delta$ associates each transition $(n, n')$ in $\rightarrow$ with a $P$-indexed family of intervals in $\mathcal{I}(N)$, such that if either $n$ or $n'$ has no $p$-event, then the $p$-component of $\Delta(n, n')$ is $[0, \infty)$.

For each $p$, we write $\Delta_p(n, n')$ for the $p$-th component of $\Delta(n, n')$. The interval $\Delta_p(n, n')$ specifies the range of relative delay on $p$ when moving from $n$ to $n'$. We write $\perp$ for the interval $[0, \infty)$. Figure 1 displays a TC-MSC graph $G_1$ whose nodes are $n_1, n_2, n_3$, with $n_1$ being the initial node and $n_2$ the final node. In $n_1$, the relative delay between the send event of $p$ and the receive event of $q$ is constrained to lie within $[0, 3]$. The $[(0, 2], \perp, \perp)$ on transition $(n_1, n_2)$ indicates $\Delta_p(n_1, n_2) = [0, 2]$, $\Delta_q(n_1, n_2) = \perp$, $\Delta_r(n_1, n_2) = \perp$. It asserts that the relative delay between the last event of $p$ of $n_1$ and the first event of $p$ of $n_2$ should be in $[0, 2]$. To reduce clutter in the figures, we omit time constraints of the form $\perp$ inside a TC-MSC labeling a node, and $(\perp)^P$ on transitions.

We fix a TC-MSC graph $G = (N, \rightarrow, n_{ini}, N_{fin}, \Lambda, \Delta)$. We write $n \rightarrow n'$ for $(n, n') \in \rightarrow$ and speak interchangeably of a node $n$ and its associated TC-MSC $\Lambda(n)$. A TC-MSC graph defines a collection of TC-MSCs arising from concatenating TC-MSCs in paths of $G$. First, for a TC-MSC $T = (E, <, \lambda, \mu, \delta)$, we call the $<_p$-minimal event in $E_p$ the first $p$-event, and the $<_p$-maximal event in $E_p$ the last $p$-event. Simply put, for a transition $(n, n')$, the concatenation of $n$ with $n'$ is the TC-MSC resulting from placing $n'$ after $n$, and for each process $p$, take $\Delta_p(n, n')$ to be the time constraint between the last $p$-event of $n$ and the first $p$-event of $n'$. Formally, letting $\Lambda(n) = (E, <, \lambda, \mu, \delta)$ and $\Lambda(n') = (E', <', \lambda', \mu', \delta')$, the concatenation of $\Lambda(n)$ and $\Lambda(n')$, denoted $\Lambda(n) \circ \Lambda(n')$, is the TC-MSC $(E''', <'', \lambda'', \mu'', \delta'')$ detailed as follows. Firstly, $E'''$ is the disjoint union of $E$ and $E''$; $\lambda''$ agrees with $\lambda$ on events in $E$, and with $\lambda'$ on events in $E''$. Secondly, for each $p$, $<''_p$ is $<_p \cup <'_p \cup E_p \times E'_p$; $\mu''$ is the union of $\mu$ and $\mu'$. Lastly, for $e, f \in E''_p$ with $e <''_p f$, $\delta''(e, f)$ is given as follows: (i) if $e, f \in E_p$, then $\delta''(e, f) = \delta(e, f)$; (ii) if $e, f \in E'$, then $\delta''(e, f) = \delta'(e, f)$; (iii) suppose $e \in E$, $f \in E'$. If for some $p$, $e$ is the last $p$-event of $n$ and $f$ the first $p$-event of $n'$, $\delta''(e, f) = \Delta_p(n, n')$, otherwise, $\delta(e, f) = \perp$. Note that the restriction $\Delta_p(n, n') = \perp$ whenever $E_p = \emptyset$ or $E''_p = \emptyset$ in Definition 2.2 is equivalent to the restrictions in $[1, 9, 2]$. It implies that $\circ$ is associative.

A path of $G$ is a sequence of nodes $\rho = n_0 \ldots n_{\ell}$ of $G$ such that $n_0 = n_{ini}$ and $n_i \rightarrow n_{i+1}$ for $i = 0, \ldots, \ell - 1$. Since $\circ$ is associative, we can unambiguously define the TC-MSC induced by $\rho$, denoted $T^\rho$, to be $\Lambda(n_0) \circ \cdots \circ \Lambda(n_\ell)$. The path $\rho$ is final if $n_\ell \in N_{fin}$. The TC-MSC _language_ of $G$ is the set of TC-MSCs induced by final paths of $G$. For a TC-MSC $T$, let $L(T)$ denote its set of timed executions. For TC-MSC graph $G$, the _timed execution language_ of $G$, denoted $L(G)$, is the union of $L(T^\rho)$ over final paths $\rho$ of $G$. We say that a TC-MSC $T$ (resp. a path $\rho$) is consistent iff $L(T) \neq \emptyset$ (resp. $L(T^\rho) \neq \emptyset$). In what follows, timed executions of the TC-MSC $T^\rho$ are sometimes referred to as timed executions of $\rho$ and $L(\rho)$ refers to $L(T^\rho)$.
We tackle the emptiness problem for TC-MSC graphs, which is: given a TC-MSC graph $G$, determine whether $L(G)$ is empty. The emptiness of $L(G)$ implies that for any TC-MSC $T^p$ induced by a final path $\rho$ of $G$, no assignment of dates to events in $T^p$ can satisfy all the time constraints in $T^p$. Thus, such a $G$ with $L(G) = \emptyset$ should be considered ill-specified, and should be checked for. However, it is known from [9] that the emptiness problem for TC-MSC graphs is undecidable. In [1, 2], decidability is obtained for locally-synchronized TC-MSC graphs. This syntactical restriction limits concurrency, and implies that the timed execution language is regular, which is a severe restriction. Indeed, even simple examples, such as $G_1$ from Figure 1 or the producer-consumer protocol, do not have regular timed execution languages.

3. Regular Set of Representatives

We advocate a technique of using regular sets of representatives (defined below) for obtaining decidability of the emptiness problem for TC-MSC graphs. This is a partial order reduction technique (since not all timed executions will be considered), which can handle TC-MSC graphs with non-regular timed execution languages. In this paper, regular will always stand for timed regular, i.e., languages accepted by finite timed automata [3]. Notice that timed regularity implies regularity of the untimed projection of the timed language.

Definition 3.1. Let $G$ be a TC-MSC graph. A subset $R$ of $L(G)$ is called a set of representatives for $G$ if for each consistent final path $\rho$ of $G$, $R \cap L(T^p) \neq \emptyset$. If further $R$ is (timed) regular, then $R$ is called a regular set of representatives.

It immediately follows that if $R$ is a set of representatives for $G$, then $L(G) = \emptyset$ iff $R = \emptyset$. Now, many timed executions of a TC-MSC graph $G$ are equivalent, in the sense that they are timed executions of the TC-MSC induced by the same final path of $G$. To check for emptiness of $L(G)$, it suffices to consider emptiness of a set $R$ of representatives for $G$, instead of $L(G)$ itself. If $R$ turns out to be regular and effective, then the emptiness problem for TC-MSC graphs can be decided. For example, consider $G_2$ in Figure 2. The language $L(G_2)$ is not regular. However, the set $\{\sigma_0, \sigma_0\sigma_1, \sigma_0\sigma_2, \ldots\}$, where $\sigma_i = (plq, 4i)(q^2p, 4i + 1)(slr, 4i + 2)(r?s, 4i + 3)$ for all $i \in \mathbb{N}$, is a regular set of representatives for $G_2$.

![Diagram](image)

Figure 2: Two TC-MSC graphs $G_2, G_3$. Specification $G_2$ is scenario-connected and $G_3$ is not.

Thus, there are three elements in the technique of regular set of representatives: (1) choose a subset $R$ of $L(G)$, (2) show that $R$ is a set of representatives for $G$ and (3) prove that $R$ is regular.

We fix TC-MSC graph $G = (N, \longrightarrow, n_{\text{ini}}, N_{\text{fin}}, \Lambda, \Delta)$, a path $\rho = n_0 \ldots n_f$ of $G$, a timed execution $w = (a_1, d_1) \ldots (a_h, d_h)$ of $\rho$, and $e_1 \ldots e_h$ the enumeration of $E$ associated with $a_1 \ldots a_h$. We start by giving a first set of representatives.

Definition 3.2. Let $K$ be an integer. We call $w$ K-drift-bounded if for each $0 \leq u \leq \ell$, and $i, j \in \{1, \ldots, h\}$, if $e_i, e_j$ are in $\Lambda(n_u)$, then $|d_i - d_j| \leq K$.

Thus $w$ is K-drift-bounded if the difference between the first and last date associated with an event of any TC-MSC $\Lambda(n_u)$ is bounded by $K$. Interpreting the scenario in each node of a TC-MSC graph as one phase or transaction of a distributed protocol, it is realistic to believe that at least some (but not necessarily all) executions of an implemented system are K-drift-bounded.

Now, for a TC-MSC graph $G$ and an integer $K$, we say that $G$ is K-drift-bounded if for every consistent path $\rho$ of $G$, there exists a K-drift-bounded timed execution in $L(\rho)$. We emphasize that all timed executions of $L(\rho)$ are not required to be K-drift-bounded. Observe that, $G$ being K-drift bounded implies that the set $L_K(G)$ of K-drift-bounded executions of $G$ is a set of representatives of $G$. Unfortunately this set may not be regular. For example, $G_2$ in Figure 2 is K-drift-bounded for $K = 1$, but $L_K(G_2)$ is not regular for any $K$. Indeed, for any $K$, the untimed projections of $L_K(G_2)$ and of $L^{0}(G_2)$, the timed language of $G_2$ where every event occurs at date 0, are the same. As the untimed projection of $L^{0}(G_2)$ is not regular, $L_K(G_2)$ is not (timed) regular.

For $K' \in \mathbb{N}$, $w$ has at most $K'$ events per unit of time if for any $i, j \in \{1, \ldots, h\}$, $d_j - d_i \leq 1$ implies $j - i < K'$. A language $L$ is strongly non-Zeno [5] if there exists $K' \in \mathbb{N}$ such that every execution of $L$ has at most $K'$ events per unit of time. It turns out that by imposing the following syntactical condition, a TC-MSC graph has a strongly non-Zeno set of representatives (this is one consequence of Theorem 4.2 below). We say that a transition $(n, n')$ of
A transition (theorems below hold with one more technical restriction) does not imply that \( L(G) \) is itself strongly non-Zeno: consider the positively constrained TC-MSC graph \( G_2 \) of Figure 2 (where transitions without labels are implicitly labeled by \( \Delta_p = \perp \) for all \( p \)). \( L(G_2) \) is not strongly non-Zeno since unboundedly many events can occur at date 0 (and hence within a unit of time). However, there exist timed executions where time elapses between positively constrained transitions.

We now present our regular set of representatives, namely the set \( \mathcal{L}_{K,K'}(G) \) of \((K,K')\)-well-behaved timed executions, as well as the restriction needed on \( G \) for representativity.

**Definition 3.3.** For \( K,K' \in \mathbb{N} \), we say that \( w \) is \((K,K')\)-well-behaved if \( w \) is \( K\)-drift-bounded and has at most \( K' \) events per unit of time. Further a TC-MSC graph is \( K\)-well-formed if it is \( K\)-drift-bounded and positively constrained.

**4. Main results**

We can now state our main results. The first two theorems below hold with one more technical restriction imposed on TC-MSC graphs. However, the third theorem will establish decidability of the emptiness problem for TC-MSC graphs even without this technical restriction. A transition \((n,n')\) of \( G \) is said to be scenario-connected if there exists a process \( p \) s.t. both \( n \) and \( n' \) have at least one \( p\)-event. \( G \) is scenario-connected if every transition of \( G \) is scenario-connected. For instance, in Figure 2, \( G_2 \) is scenario-connected while \( G_3 \) is not.

**Theorem 4.1.** Let \( K,K' \in \mathbb{N} \). If \( G \) is scenario-connected, then \( \mathcal{L}_{K,K'}(G) \) is (timed) regular.

For representativity, we need \( G \) to be well-formed.

**Theorem 4.2.** Let \( K \in \mathbb{N} \). If \( G \) is \( K\)-well-formed and scenario-connected, then \( \mathcal{L}_{K,K'}(G) \) is a set of representatives of \( G \), with \( K' = (4(|P| + 1) + 2) \cdot |P| \cdot M \), where \( M \) is the max number of events in a node of \( G \).

Subsequently, in Proposition 5.3, we will prove that we can lift the the scenario-connected assumption, which along with Theorems 4.1 and 4.2 implies:

**Theorem 4.3.** Given a \( K\)-well-formed TC-MSC graph \( G \) for some integer \( K \), it is decidable to determine whether \( L(G) = \emptyset \).

An immediate question is if, given a TC-MSC graph \( G \) and an integer \( K \), one can decide whether \( G \) is \( K\)-well-formed. In fact, it turns out that this question is decidable. However, its proof involves vastly different techniques, and will be dealt with in a subsequent paper (see [16] for a draft).

**5. Proofs of Main Results**

**Regularity:** We prove Theorem 4.1 by constructing a timed automaton \( A \) which recognizes \( \mathcal{L}_{K,K'}(G) \). As in [15], \( A \) keeps track of nodes that have not yet been fully executed, plus unexecuted events of these nodes. The property proved in Lemma 5.2 shows that it suffices to remember finitely many nodes and events (and thus finitely many clocks). Throughout this section, let \( K,K' \in \mathbb{N} \), and \( \rho = n_0 \ldots n_z \) a (non necessarily final) path of a scenario-connected TC-MSC graph \( G \). Let \( w = (a_1,d_1) \ldots (a_t,d_t) \) be a \((K,K')\)-well-behaved timed execution of \( \rho \). We denote by \( e_1,\ldots,e_t \) the enumeration of events of \( T^\rho \) associated with \( a_1,\ldots,a_t \), and \( d(e_i) = d_i \) for all \( i \). We also fix two constants \( C_\rho = (|P| + 1) \cdot K \), and \( C_{K,K'} = 2 \cdot |P| \cdot K' \cdot C_\rho \).

**Lemma 5.1.** Let \( g \) be an event of node \( n_j \) and \( g' \) of node \( n_{j'} \) of \( \rho \), with \( j \leq j' \). Then \( d(g) \leq d(g') + C_\rho \).

Proof. Since \( G \) is scenario-connected, it follows that for each \( n_i \) of \( \rho \), there exists a process \( p_i \), an event \( f_i \) in \( n_i \) and an event \( g_i \) in \( n_{i+1} \) such that both \( f_i,g_i \) are on process \( p_i \). Thus, there exists a subsequence of \((f_i,g_i)\) consisting of \( k \leq |P| \) pairs \((f_{o(i)},g_{o(i)})\) satisfying the following: (1) \( f_{o(i)} \) and \( g_{o(i)} \) are in the same node, (2) \( f_{o(i+1)} \) and \( g_{o(i)} \) are in the same node for all \( i < k \), (3) \( g' \) and \( g_{o(k)} \) are in the same node and (4) \( f_{o(i)} \) and \( f_{o(i')} \) are on different processes for all \( i \neq i' \). Then, we have \( f_{o(i)} < g_{o(i)} \) for each \( i \leq k \), as they are on the same process. Hence \( d(f_{o(i)}) \leq d(g_{o(i)}) \).

Also, \( d(g) - d(f_{o(i)}) \leq K \) since \( g,f_{o(i)} \) are in the same node. Similarly, \( d(f_{o(i+1)}) - d(g_{o(i)}) \leq K \) for each \( i \leq k \), and \( d(g_{o(k)}) - d(g') \leq K \). Thus, \( d(g) \leq d(g') + (|P| + 1) \cdot K \) (since \( k \leq |P| \)).

The next lemma is the key for the regularity.

**Lemma 5.2.** Let \( n_x \) be a node of \( \rho \) such that \( x - x \geq C_{K,K'} \). For all \( e \in n_x \) and \( f \) in \( n_z \), \( d(e) < d(f) \).

Proof. Recall that \( w \) has at most \( K' \) events per unit of time, and that each node of \( \rho \) contains at least one event. As \( z - x \geq C_{K,K'} \), there are \( m \geq 2K' \times C_K \) events \( f_1 < \ldots < f_m \) in \( n_x \) and
Let $G$ be a timed graph. It is easy but tedious to show that the last event of node $n_z$ appearing in $w$, every node $n_{x_2}$ with $x_2 < x - z - C_{K'}$, has been fully executed before $a_i$: for every event $a_i$ of $n_{x_2}$, we have $i < k$. We can now sketch the construction of the timed automaton $A$.

- States of $A$ are sequences $(n_1, S_1) \cdots (n_k, S_k)$, such that $k \leq C_{K,K'}$, $n_1 \cdots n_k$ is a (not necessarily initial or final) path of $G$, for all $i$, $S_i$ is a suffix (for $<n_i$) of $\Lambda(n_i)$ and $S_i \neq \emptyset$. For each $j$, we can restrict to $k \leq C_{K,K'}$ using Lemma 5.2. There is a clock associated with every event $e$ in $\bigcup_{n \in \{1, \ldots, k\}} \Lambda(n_i)$, called the e-clock, and every process $p \in \mathcal{P}$, called the p-clock.

- $(n_1, S_1) \cdots (n_k, S_k) \rightarrow (n'_1, S'_1) \cdots (n'_k, S'_k)$ is a transition of $A$ if one of the following holds:

  - **Action**: $k = k'$, $n'_j = n_j$ for all $j$, there exists $i$ with $S_i = e \cdot S_i'$ and $S_i' = S_j$ for all $j \neq i$. Further, $S_1 \cdots S_{i-1}$ has no event on $p(e)$. The guard states that for all $f$ in $n_i$, the f-clock is in $\delta(f,e)$, and if $e$ is the first event of $n_i$ on $p$, then the p-clock is in $\Delta_p(n_i-1, n_i)$. The transition resets the e-clock. Further, if $e$ is the last event of $n_i$ on $p$, then it resets the p-clock.

  - **New Node**: $k' = k + 1 \leq C_{K,K'}$, $(n'_1, S'_1) \cdots (n'_k, S'_k) = (n_1, S_1) \cdots (n_k, S_k)$, $n_{k+1} \rightarrow n'_k$ and $S'_k = \Lambda(n'_k)$.

  - **Deletion**: $k > 1, k' = k - 1, S_1 = \emptyset$ and $(n'_1, S'_1) \cdots (n'_k, S'_k) = (n_2, S_2) \cdots (n_k, S_k)$.

It is easy but tedious to show $L(A) = L_{K,K'}(G)$.

**Representativeness**: Now, we prove Theorem 4.2. Let $\rho = n_0 \cdots n_2$ be a consistent path of $G$. As $G$ is K-drift-bounded, there is a K-drift-bounded timed execution $w = (a_1, d_1) \cdots (a_t, d_t)$ of $T^\rho$. We construct another timed execution $w' = (a_1, d'_1) \cdots (a_t, d'_t)$ from $w$ by suitably modifying the dates such that $w'$ is still an execution of $T^\rho$ and $w'$ is K-drift-bounded with at most $K' = (4C_{K} + 2) \cdot |\mathcal{P}| \cdot M$ events per unit of time, where $M$ is the largest number of events in a node of $G$. The key idea in the construction of $w'$ is to inductively postpone (when needed) the dates of all events of $n_x \cdots n_z$. By postponing, we ensure that there will exist some process $p$ such that the difference between the date of the last p-event of $n_{x-1}$ and the date of the first p-event of $n_z$ is at least $1/2$. We use $1/2$ since all intervals have integer bounds. We do not postpone if it is already the case.

As before, let $e_1 \cdots e_t$ be an enumeration of events in $T^\rho$ corresponding to $a_1 \cdots a_t$, and let us write $d(e)$ (resp. $d'(e)$) for the date $d_i$ (resp $d'_i$), when $e = e_i$. To construct $w'$, we first initialize $d'(e) = d(e)$ for each event $e$. Next, consider node $n_1$. Let $Q$ be the set of processes $p$ that participate in both $n_0$ and $n_1$. As $G$ is scenario-connected, $Q \neq \emptyset$. For each $p$ in $Q$, let $l_{ep}(n_0)$ denote the last p-event of $n_0$ and $f_{ep}(n_1)$ denote the first p-event of $n_1$. If for some $p \in Q$, $d(f_{ep}(n_1)) - d(l_{ep}(n_0)) \geq 1/2$, then for each event $e$ in $n_1$, do not modify $d'(e)$ (it will not be modified later either). Otherwise, let $\theta_{max} = 1/2$ be the maximum of $d(f_{ep}(n_1)) - d(l_{ep}(n_0))$ where $p$ ranges over $Q$. For each event $e$ in $n_1 \cdots n_z$, set $d'(e) = d(e) + 1/2 - \theta_{max}$. We emphasize that when considering node $n_1$, the above procedure postpones dates of events in $n_1$, and dates of events in $n_2 \cdots n_z$, by the same amount. Since $G$ is positively constrained, the timed execution resulting from the above procedure is still in $L(T^\rho)$ and is still K-drift-bounded. We inductively carry on the above procedure to consider each of the nodes $n_2, \ldots, n_z$. The timed execution $w'$ is obtained after considering all the nodes $n_0, \ldots, n_z$. It follows that $w'$ is K-drift-bounded and is in $L(\rho)$.

It remains to show that $w'$ has at most $K'$ events per unit of time. It suffices to show that every pair of events $e, f$ from two nodes $n_x, n_z$ with $z \neq x > C = (4C_{K} + 2) \cdot |\mathcal{P}|$ satisfies $d'(f) > d'(e) + 1$. Indeed, then, for each $t$, the set of events $e$ with $d(e) \in [t, t+1)$ is included into the set of events of $n_y \cdots n_{y+c}$ for some $y$. There are at most $K' = C \times M$ such events, hence there are at most $K'$ events per unit of time.

If there are more than $C = (4C_{K} + 2) \cdot |\mathcal{P}|$ nodes between $n_x$ and $n_z$, then there is some process $p$ and more than $4C_{K} + 2$ pairs $(f_i, g_i)$ of events in $n_x \cdots n_z$ with $f_i$ the last $p$-event on some node $n_{x+i}$, $g_i$ is the first event on node $n_{x+i+1}$, $d'(g_i) - d'(f_i) \geq 1/2$, and $\alpha$ is strictly increasing. This is by construction of $w'$. That is, $d'(f_i) + 2C_{K} + 1 < d'(g_{i+1}) + C_{K} + 1 < d'(g_{i+2}) - 2C_{K} + 1 + C_{K} + 1 \leq d(f_i)$.
Decidability: From Theorems 4.1 and 4.2, we readily conclude that, if \( G \) is scenario-connected, and \( K \)-well-formed, then one can decide whether \( L(G) \) is empty. It remains to lift the scenario-connected restriction to prove Theorem 4.3. Suppose \( G \) is not scenario-connected. Let \( NSC \) denote the set of transitions of \( G \) that are not scenario-connected. Proposition 5.3 states the crucial observation that for any path \( \rho = n_0 \cdots n_\ell \) with \( (n_i, n_{i+1}) \) in \( NSC \) for some \( i \), the dates of events in \( n_{i+1} \cdots n_\ell \) are not constrained in any way by the dates of events in \( n_0 \cdots n_i \). This fact was also used in [9] along the same lines. Recall that in a transition \( (n, n') \), if some \( p \in \mathcal{P} \) does not participate in either \( n \) or \( n' \), then \( \Delta_p(n, n') = \perp = [0, \infty) \).

Proposition 5.3. Let \( \rho = n_0 \cdots n_\ell \) a path of \( G \).
If \( (n_i, n_{i+1}) \) is in \( NSC \) then \( \rho \) is consistent iff both \( n_0 \cdots n_i \) and \( n_{i+1} \cdots n_\ell \) are consistent. If \( \rho \) is consistent, \( (n_i, n_{i+1}), (n_j, n_{j+1}) \) are both in \( NSC \) and \( n_i = n_j \), then \( n_0 \cdots n_j n_{j+1} \cdots n_\ell \) is also consistent.

We now decompose \( G \) into a finite collection \( \mathcal{H} \) of TC-MSC graphs, each of which is scenario-connected. We will decide the non-emptiness of \( L(G) \) by considering the non-emptiness of \( L(H) \) for every \( H \) in \( \mathcal{H} \), which is decidable as shown earlier. Let \( N_1 \) be the subset of nodes \( n \) of \( G \) such that \( (n', n) \in NSC \) for some node \( n' \) of \( G \). Let \( N_2 \) be the subset of nodes \( n' \) of \( G \) such that \( (n', n) \in NSC \) for some node \( n \) of \( G \). For each \( n \in N_1 \cup \{n_{ini}\} \), each \( n' \in N_2 \cup N_{fin} \), we build the scenario-connected TC-MSC graph \( H_{n,n'} \) from \( G \) as follows. The set of nodes of \( H_{n,n'} \) is the same as \( G \). \( H_{n,n'} \) has \( n \) as initial node, and has one single final node \( n' \). The transitions of \( H_{n,n'} \) consist of all scenario-connected transitions of \( G \). Let \( \mathcal{H} \) be the collection of all such \( H_{n,n'} \). For each \( H_{n,n'} \) in \( \mathcal{H} \), we can decide whether \( L(H_{n,n'}) \) is empty since it is scenario-connected. From Proposition 5.3(1), \( L(G) \) is not empty iff there exist a sequence \( H_{n_0,n_1}, H_{n_2,n_3}, \ldots, H_{n_{2\ell},n_{2\ell+1}} \) in \( \mathcal{H} \) such that \( n_0 = n_{ini}, n_{2\ell+1} = N_{fin}, \) and for each \( i \leq \ell \), \( L(H_{n_2i,n_{2i+1}}) \) is not empty and \( (n_{2i+1}, n_{2i+2}) \) in \( NSC \). We can choose \( n_0, n_2, \ldots, n_{2\ell} \) to be distinct according to Proposition 5.3(2). In particular, \( \ell \) is at most the number of nodes of \( G \).

6. Conclusion

In this paper, we have proved decidability of the language emptiness problem for a subclass of TC-MSC graphs. This problem was known to be undecidable in general and decidable for regular TC-MSC graphs. The subclass considered in this paper contains non-regular specifications and thus non-trivially extends the boundary of decidability. It is characterized in terms of bounds on the time a basic scenario takes, and disallows the constraint \([0, 0]\) on transitions. We believe (see also [17]) that these two requirements do not impair implementability, and meet what designers have in mind when designing a TC-MSC graph: event execution takes time, and the specification is split in phases.

Appendix

We give here the proof of Proposition 5.3.

**Proposition 5.3.** Let $\rho = n_0 \cdots n_{\ell}$ a path of $G$. (1) If $(n_i, n_{i+1})$ is in NSC then $\rho$ is consistent iff both $n_0 \cdots n_i$ and $n_{i+1} \cdots n_\ell$ are consistent. (2) If $\rho$ is consistent, $(n_i, n_{i+1})$, $(n_j, n_{j+1})$ are both in NSC and $n_i = n_j$, then $n_0 \cdots n_i n_{i+1} \cdots n_\ell$ is also consistent.

We start by assuming wlog that a given TC-MSC graph $G$ has a unique initial node $n_0$ and final node $n_\ell$ (else we can add a dummy initial node and edges from it to the old initial nodes and a dummy final node with edges from the old final nodes to this one). Recall that $(n_1, n_2) \in$ NSC if the processes that participate in $n_1$ and $n_2$ are disjoint. Observe that such edges are *unconstrained* by definition, i.e., they can only have the timing constraint $\perp = [0, \infty)$.

**Proof.** (1) One direction is straightforward. If $\rho$ is consistent, then it means that we have a dated execution $(w, d)$ corresponding to $T^\rho$. Now, projecting $(w, d)$ to events of $n_0 \cdots n_i$ and $n_{i+1} \cdots n_\ell$, we respectively obtain a dated execution generated by $T^{n_0 \cdots n_i}$ and $T^{n_{i+1} \cdots n_\ell}$. Thus, both $T^{n_0 \cdots n_i}$ and $T^{n_{i+1} \cdots n_\ell}$ are consistent.

For the other direction, assume that both $T^{n_0 \cdots n_i}$ and $T^{n_{i+1} \cdots n_\ell}$ are consistent, with timed executions $(w_1, d_1)$ and $(w_2, d_2)$. We can then obtain the timed execution $(w_1 w_2, d)$ of $T^\rho$ by delaying the timings sufficiently. More precisely, the timing $d$ is obtained as $d(e) = d_1(e)$ for $e \in n_0 \cdots n_i$, and $d(e) = d_2(e) + \max$ for $e \in n_{i+1} \cdots n_\ell$, where max is the latest timing in $d_1$. Indeed, such a delay in the events is possible because we know that the edge $(n_i n_{i+1})$ is unconstrained and so a constant delay in all the events will not affect any constraint in this execution $T^\rho$. Thus $(w_1 w_2, d)$ is a timed execution of $T^\rho$ completing part (1) of the proof.

(2) Finally, assume that $\rho$ is consistent, $(n_1, n_{i+1})$, $(n_j, n_{j+1})$ are both in NSC and $n_i = n_j$. Consider a timed execution $(w, d)$ of $T^\rho$. We first project it to events of $n_1 \cdots n_i$ to obtain the timed execution $(w_1, d_1)$. We also project it to events of $n_j + 1 \cdots n_\ell$ to obtain the timed executions $(w_2, d_2)$. Now, as above, the timed execution $(w_1 w_2, d')$ with $d'(e) = d_1(e)$ for $e \in n_0 \cdots n_i$, and $d'(e) = d_2(e) + \max$ for $e \in n_{i+1} \cdots n_\ell$, where max is the latest timing in $d_1$ is an execution of $T^{n_0 \cdots n_i n_{i+1} \cdots n_\ell}$, which is thus consistent. \hfill $\Box$

With the above proof of Proposition 5.3, let us now demonstrate how the proof of Theorem 5.3 (decidability) works on a simple example. Consider the graph $\tilde{G}$ in Figure 3. Then $(n_1, n_2)$ and $(n_2, n_1)$ are unconstrained edges and $N_1 = \{n_0, n_2\}$ and $N_2 = \{n_1, n_2\}$ (the definitions of the sets $N_1$ and $N_2$ are as in the last paragraph of Section 5). The graph decomposition consists of $\tilde{H}_{n_0, n_1}$ and $\tilde{H}_{n_2, n_2}$ in the picture. Now observe that both $\tilde{H}_{n_0, n_1}$ and $\tilde{H}_{n_2, n_2}$ are consistent (that it there exist accepting paths) and $(n_1, n_2)$ is unconstrained in $\tilde{G}$. Thus by Proposition 5.3 $n_0 n_1 n_2$ is consistent and hence $L(\tilde{G})$ is non-empty, which indeed is also clear from the picture.
